Abstract: The benefits of photovoltaic systems are not only for electricity generation, but also provide shading for building envelopes to reduce heat gain from solar radiation. However, a crucial problem of photovoltaic system installation on building envelopes is an increase of photovoltaic module’s temperatures due to insufficient ventilation. An appropriate air spacing of the enclosure, which minimizes the heat gains through walls/roofs and maximizes photovoltaic electricity generation, has not been studied extensively and is not well documented. In this study, an adjustable testing rig model was designed and constructed. It is capable of varying the air space and the inclination angle of a photovoltaic system. The test rig was initially set up to be tilted at the same degree of Bangkok’s latitude (oriented due to southward, at 15° of tilted angle) and spacing of air gap 140 mm. An actual experimental test was used to verify a simulation model. The experimental results indicate that the model can predict relatively well for the module’s temperatures, but with some discrepancy for the wall surface temperatures. After that it was simulated under the same condition in various the spacing of the air gap from 10 mm to 250 mm with 10 mm increment. The results shown that, the appropriate air gap can reduce the amount of heat transferred into building at least 1.85 kWh/m² per year. Although the increase of the air gap spacing tends to reduce the heat gain through the building, the spacing of the air gap is limited due to an increase of the unshaded area and increases outside temperatures of the building, which, in turn, the heat gain through the building is increased.

Keywords: Photovoltaic, Heat Gain, Air Gap, Building Envelop, Enclosure, Energy Balance Method, Simulation

1. INTRODUCTION

In Thailand, about 60% of electricity in buildings is consumed by air conditioning loads because it is located on the hot humid tropics. There are a few possible solutions to reduce the electricity load demands of air conditioning systems, which are either to reduce heat gains through the building, or to prevent the building envelopes from exposure to the solar radiation by using shading devices. One of possible methods is to mount photovoltaic panels to cover building envelopes, which is called as photovoltaic cladding. This method can reduce amounts of the direct sunlight incident on the building envelopes and, on the same time, they can also provide clean electricity generation.

Nevertheless, there is a disadvantage in mounting the photovoltaic panel on the building envelope. It will increase the photovoltaic module’s temperatures due to the long wave emissive radiation from the building envelope to the photovoltaic panel, if the ventilation is insufficient on the back of the photovoltaic panel. Photovoltaic performance is generally deteriorated due to the rise of module’s temperature, i.e. 0.3-0.6% per 1°C for crystalline silicon and 0.2% per 1°C for thin film silicon [1]. The performance of photovoltaic panel on the building can be improved, if there is a sufficient space of the air gap underneath the photovoltaic modules. The sufficient air gap can lead to dissipate the rate of heat transfer from the photovoltaic panel, and decreases in the module’s temperatures. However, the space of the air gap between the photovoltaic module and the building envelope should not be too large otherwise it may lead to an unaesthetic appearance, a damage caused by the lift-force, an increase in unshaded areas and resulted in more direct solar radiation incident on the building envelopes, which causes to increase the heat gain through the building.

The influences of photovoltaic panels on the heat transfer through building envelop and photovoltaic performance has been studied. The study on the effect of an air flow induced by free convection behind the photovoltaic panels has been studied by Brinkworth et al. [2], they found that the air flow induced by buoyancy force can reduce the module’s temperature up to 20 K. Yang et al. [3] built a test rig of a photovoltaic-wall and photovoltaic roof for validation their simulation model. The well design of ventilated photovoltaic-wall structure can reduce the module’s temperature up to 15°C and increase 8.0% of the power output compared with non-ventilation. The results of Brinkworth’s study [2] have been presented not only the effect of the module’s temperature, but also the effect of shading by the photovoltaic cladding. It is noted that the peak temperature of the outer surface of the wall is reduced from 50°C to 32°C for without and with PV shading, respectively, and heat gain received through a building of 105.6 kJ/m² is reduced over a day. The closing and opening of the entrance of air gap behind photovoltaic module also influence on the module’s temperature. Brinkworth et al. [4] found that the temperature difference between the closing and the opening air entrance is 26°C. This high temperature difference occurred because the closing air entrance led to the poor heat transfer on the rear surface of photovoltaic module.

In this paper, the appropriate air gap underneath photovoltaic panels on building envelopes has been investigated using a simulation method whose validity is verified from experimental results. The appropriate air gap is required in order to minimize the heat gain to and maximize the electricity generation from the photovoltaic panels. The present work is focused on the gap configuration in the enclosure of the non-ventilated air gap, which is the condition of the poorest photovoltaic installation on building envelopes. The inclined surface is set at 15° and the air gap is varied from 10 to 250 mm with 10mm increment. A simulation model has been developed based on the energy balance method with the assumptions of unsteady state conditions and one-dimensional heat transfer.

2. METHODOLOGY

2.1 Experimental set up

A test rig of a photovoltaic panel on a building envelope was set up and tested in the actual outdoor climatic conditions of Thailand, at Bangkhunthian campus, King Mongkut University of Technology Thonburi (KMUTT). Testing data were recorded automatically using Campbell datalogger “CR10X”, which was programmed to read data every 10 seconds and the collected data were averaged every one minute and one hour. The test rig contains an 80 W multi-crystalline silicon photovoltaic module which is mounted on lightweight blocks. The blocks were plastered by mortar on both the front and the rear surface, which are a basic method of the building envelopes constructed in Thailand. A room beneath the building envelope platform was constructed and enclosed with multilayer insulators and controlled at a constant temperature at 25°C, by an air conditioning unit. The periphery of the air gap, which is the space between the photovoltaic module and the building envelopes, was enclosed with insulation as an enclosure space.

The constructed testing rig is supported by four steel stands, and the rig was designed in such a way that it can be adjustable in various inclination angles and air gap spaces as shown in Fig.1. A pyranometer is mounted on the same plane as of the photovoltaic panels. K-type thermocouples were adhered at the middle of each surface such as the front and the rear of the photovoltaic panel, the front and the rear of the building envelopes within the enclosure air gap, and the temperature-controlled free space room.

For the measurement of climatic data, Campbell weather station was set up to measure the wind velocity and direction, the solar irradiance, the ambient temperature, and the relative humidity, and recorded by a Campbell datalogger.

Fig. 1 System schematic of a photovoltaic panel on building envelope

Fig. 2 (a) Photovoltaic panel on building envelop in the field test, and (b) Setting the air gap as an enclosure

2.2 Testing Conditions

In the present work, the photovoltaic testing rig was set up on a condition of which a photovoltaic panel on building envelopes has the poorest ventilation i.e. there is no ventilation beneath the photovoltaic panel at all. Under this condition, it leads to high temperature of photovoltaic panel and poor heat exchange to surroundings when the sky is clear during a day time, and hence it decreases in the photovoltaic performance. The air gap underneath the photovoltaic module of the test rig was enclosed around with insulation foam on the outside perimeter of all walls as shown in Fig.2. The air gap is 140 mm high and is tilted at 15 degree of the inclined surface due to the south. Under this condition, the photovoltaic panel receives the highest solar irradiance. Measurements of the actual temperatures of each surface, the amounts of generated electricity and the weather data were recorded and used for verifying the accuracy of the simulation model.
2.3 Process of heat transfer on photovoltaic panel and the building

2.3.1 Energy balance on photovoltaic panel

The heat absorption at a photovoltaic panel, which can be all converted into electricity, the accumulated heat on itself and the heat losses to surroundings can be written as:

\[
\dot{I}_i\alpha_{prc} = h_f(T_{prc} - T_{amb}) + h_d(T_{prc} - T_{sky}) + h_{ine}(T_{prc} - T_a) + h_{rinh}(T_{prc} - T_{wo}) + \dot{I}_i\eta_{ztc}(1 - 0.005(5(T_{prc} - 25))) + \frac{m_{prc}C_{prc}\frac{dT_{prc}}{dt}}{A_{prc}}, \tag{1}
\]

where \(\dot{I}_i\) is the solar radiation incident on tilted surface, \(\alpha\) is the absorptivity of the cell, \(T_{prc}\) is the transmitivity of the glass, \(h_f\) and \(h_d\) are respectively the heat convection coefficient and the thermal radiation coefficient on the front surface of the photovoltaic panel, \(h_{ine}\) is the heat convection coefficient in the enclosed air gap between the rear surface of photovoltaic and the air, \(h_{rinh}\) is the thermal radiation coefficient between the photovoltaic and the top surface of the top wall, \(T_{prc}\) is the module’s temperature, \(T_{amb}\) is the ambient temperature, \(T_{sky}\) is the sky temperature, \(T_a\) is the air temperature in the enclosed air gap, \(m_{prc}\) is the mass of photovoltaic panel, \(C_{prc}\) is the heat capacity of photovoltaic panel, \(A_{prc}\) is the surface area of photovoltaic panel, \(\eta_{ztc}\) is the photovoltaic’s efficiency at the standard testing condition, and \(dt\) is the interval time.

![Fig. 3 The heat transfer processes on the photovoltaic module on building envelop](image)

Shortwave radiation, \(\dot{I}_g\), the revised ASHRAE clear sky model, that was developed from five-year data of four-province solar radiation during years 1996-2000 by Amarananwatana et al. [5], is applied in this work to determine the solar intensity of Thailand under clear sky condition.

\[
\dot{I}_g = \dot{I}_s \cos \theta_z + \dot{I}_d, \tag{2}
\]

\[
\dot{I}_s = A \exp(-B \sec \theta_z), \tag{3}
\]

\[
\dot{I}_d = C \dot{I}_s, \tag{4}
\]

where \(\dot{I}_g\) is the global irradiance on horizontal surface, \(\dot{I}_s\) is the direct irradiance on horizontal surface, \(\dot{I}_d\) is the diffuse irradiance on horizontal surface, \(A\), \(B\) and \(C\) are the correction factor due to extraterritorial irradiance, atmospheric attenuation, and diffuse radiation, respectively, and \(\theta_z\) is the zenith angle.

Ambient temperature, \(T_{amb}\), the ASHRAE air temperature model [6] is used to calculate the outdoor air temperature for the extreme condition, which is given by

\[
T_{amb} = T_{max} - \frac{f}{100} (T_{max} - T_{min}), \tag{5}
\]

where \(T_{max}\) and \(T_{min}\) are the maximum and minimum temperature from the local meteorological, and \(f\) is the daily range.

Sky temperature, \(T_{sky}\), is based on Idso-Jackson model [7], which was an empirical formula of downward radiation, developed from experiment data based on a theoretical study of those parameters which influence on the emissivity of the atmosphere.

\[
T_{sky} = \frac{R_e + (\sigma T^4 - R_e)F}{\sigma}, \tag{6}
\]
when
\[ R_w/\alpha T^4 = 1 - 0.261 \text{Exp}\left[-7.77 \times 10^{-4} (273 - T)^2\right] , \tag{7} \]
where \( R_w \) is the downward atmospheric radiation flux from a clear sky, \( T' \) is the absolute screen level air temperature, \( F \) is the correction factor from the effect of cloud \([8]\), and \( \alpha \) is the Stefan-Boltzman constant.

**Heat convection coefficient**, the heat convection on its surface, \( h_{cf} \), is dominated by the effect of wind velocity, \( V_w \), which is given by McAdams \([9]\)
\[ h_{cf} = 5.7 + 3.8V_w \quad \text{for} \quad 0 < V_w < 7 \text{ m/s}, \tag{8} \]
In enclosed air gap, under a situation of which the heat transferred is dominated by the free convection, it is calculated from the effect of the inclination angle and dimensionless numbers: the Nusselt number, \( Nu \), the Rayleigh number, \( Ra \), and the Prandtl number, \( Pr \).

**Table 1** Heat coefficient equations of free convection in the enclosure in various planes \([10]\)

<table>
<thead>
<tr>

<tbody>
<tr>
<td></td>
<td>( Nu = 1 + 0.446{1 - (1,708 / Ra \cdot \cos \beta)} )</td>
<td>( 1,708 \leq Ra \cdot \cos \beta &lt; 5,900 )</td>
</tr>
<tr>
<td></td>
<td>( Nu = 0.229(Ra \cdot \cos \beta)^{2.32} )</td>
<td>( 5,900 \leq Ra \cdot \cos \beta &lt; 9.24 \times 10^4 )</td>
</tr>
<tr>
<td></td>
<td>( Nu = 0.157(Ra \cdot \cos \beta)^{3.23} )</td>
<td>( 9.24 \times 10^4 \leq Ra \cdot \cos \beta &lt; 10^6 )</td>
</tr>
</tbody>
</table>

where \( H \) is the length of photovoltaic module and \( S \) is the width of airspace.

Therefore, the heat convection coefficient is calculated from the equation, which is given by
\[ h = \frac{Nu \cdot k}{S}, \tag{9} \]

**Longwave radiation coefficient**, there are two longwave radiation coefficients which are involved in the calculation: the first one is \( h_{rf} \), the longwave radiation coefficient between the photovoltaic module and the ambient, which can be expressed as
\[ h_{rf} = \sigma \epsilon_{pv} (T_{pv}^2 + T_{sky}^2)(T_{pv} + T_{sky}), \tag{10} \]
The second one is \( h_{ra} \), the heat radiation coefficient between the rear surface of the photovoltaic module (or Tedlar) and the top wall surface of the building material that can be written as:
\[ h_{ra} = \frac{\sigma \left(T_{pv}^2 + T_{wall}^2\right)(T_{pv} + T_{wall})}{(1/ \epsilon_{wall}) + (1/ \epsilon_{slab}) - 1}, \tag{11} \]
where \( \epsilon \) is the emissivity of surface material.

### 2.3.2 Energy balance of the air mass in the gap space
The air gap is assumed to be perfected enclosure, the air flow in the gap, therefore, can be ignored. The heat balance of air in the enclosure can be calculated from the accumulated heat on the air mass in the enclosure and the absorbed (or emitted) heat transferred from the photovoltaic module and the building envelopes, which is given by
\[ \frac{d}{dt} \left( M \cdot C_p \right) + (A_{pv} - A_{wall}) \frac{C_p}{A_{wall}} \frac{dT_{pv}}{dt} - A_{wall} \frac{C_p}{A_{wall}} \frac{dT_{wall}}{dt}, \tag{12} \]
where \( h_{wc} \) is the convection coefficient of the top surface of the wall with the air in the enclosure, and \( m_a, C_p, \) and \( T_a \) are the mass, the heat capacity and the temperature of the air in the enclosure respectively.

### 2.3.3 Energy balance on the top surface of the top wall (or roof)
The heat balance on the top of the top wall (roof) surface can be calculated from the long wave radiation exchanges between the photovoltaic panel’s rear surface and the top wall’s surface, the heat convection of air at the top wall’s surface within the enclosed air gap, and the heat penetration (released) by conduction into (from) the surface of the top wall (roof) to the first inner layer of building materials at temperature node of \( T_{i,j} \):
\[ h_{wc} \left(T_{pv} - T_{wall}\right) + h_{ra} \left(T_{wall} - T_{a}\right) = \frac{m_a C_p}{A_{wall}} \frac{dT_{wall}}{dt}, \tag{13} \]
where \( R_{in} \) is the thermal resistance of the ith wall layer, \( T_{i,j} \) is the temperature at a given inner layer jth and at a point j.

**Heat conduction coefficient of the building material**, can be calculated from the conductance of material, with respect to its thickness. The transient heat transfer is applied and a wall layer could be assumed to be a uniform temperature of a single value, provided that its Biot number, \( Bi \), is less than 0.1.
\[ Bi = \frac{hL}{k}, \tag{14} \]
where \( h \) is the heat convection coefficient, \( L \) is the characteristic length of the object, and \( k \) is the thermal conductivity of material.

The heat conduction resistance of the material, \( R \), is
\[ R = \frac{L}{k}, \tag{15} \]
2.3.4 Energy balance in the building material

Normally, the heat transfer across the building material (wall/roof) can be simplified by one-dimensional analysis. The wall comprises of several thin sections of homogeneous material, and each of them can be represented by a single temperature for the entire interior of that section. In this study, the finite difference method is applied in the simulation model to study the heat transfer in the building material. The energy balance for an interior point can be computed from the heat balance of the accumulated heat in the layer and the heat conduction as given below:

\[
\frac{\Delta x \rho C_p}{dt} (T_{i,j} - T_{i-1,j}) = \frac{T_{i+1,j} - T_{i,j}}{R_{\text{th}} + R_{\text{c}}} - \frac{T_{i,j} - T_{i,j-1}}{R_{\text{th}} + R_{\text{r}}} ,
\]

(16)

where \( \Delta x \) is the thickness of wall layer.

2.3.5 Energy balance on an inner surface of the wall

The heat balance on an inner surface of the wall is dominated by the heat conduction and the heat transfer coefficient of the combination between the convection and the radiation in the indoor room, \( h_i \), which is given by

\[
h_i(T_{wi} - T_i) = \frac{T_{wi} - T_i}{R_{\text{th}}} ,
\]

(17)

where \( T_i \) is the room temperature, which is fixed at 25°C, \( T_{wi} \) is the surface temperature of the inner wall.

2.3.6 The heat gain through building

According to the heat conduction, the calculation of this simulation is examined by using the finite difference method. The heat gain through the building can be computed from the heat transfer between the surface temperature of the inner wall and the air temperature inside the room.

\[
q^* = h_i(T_{wi} - T_i) ,
\]

(18)

where \( q^* \) is the total heat flux into building.

2.4 The simulation method

The simulation model was programmed by using MATLAB software, based on the above equations as shown in Fig.4. The capability of the program can determine the annual heat gain through the building and the annual electricity energy outputs from the photovoltaic panel mounting on the building envelops under the clear sky condition of Thailand, which is considered to be the maximum possible electricity outputs available, while minimize the heat load transferred to the building envelop. The model is based on the following assumptions: (i) the heat transfer is one-dimensional, (ii) the thermal-physical properties of photovoltaic elements and building materials are independent of temperature within the test conditions, (iii) the temperatures uniformly distribute within materials, (iv) the temperature difference between the front and the rear surface of the module is neglected and (v) the effect of heat capacity from aluminum frame of photovoltaic panel is ignored. The physical properties of photovoltaic components and the building materials are given in Table 2.

3. RESULTS OF STUDY

3.1 Accuracy of simulation model and verification

Prior to use the simulation model for evaluating the amount of annual heat flux passing into a building and the annual electricity generating under the extreme condition of Thailand, the model should be verified its accuracy with experimental data. The model performance is assessed by using experimental data under the testing conditions of 15° tilted angle, the facing due south and 140 mm air spacing, and statistical analyses: the root mean square error (RMSE) and the mean bias error (MBE). RMSE is calculated to assess the magnitude of the accuracy of the predicted data, whereas, MBE is used to identify the systematic error of the predicted data whether it is overestimation or underestimation from the actual values. The comparison of RMSE, MBE, % Error of RMSE and % Error of MBE of predictions, as compared the corresponding mean values, between the module’s temperature and the top of the wall temperature is given in Table 3 and shown in Fig. 5.

The average value of RMSE of the module’s temperature is 1.843°C, the surface temperature of the top wall is 4.816°C, the surface temperature of the inner wall is 6.708°C, and the air temperature in the gap is 2.141°C, indicate that the simulation model give a better accuracy in the prediction of the module’s temperature than the air temperature in the enclosed air gap, the surface temperature of the top wall, and the surface temperature of the inner wall, respectively. The magnitude of MBE is -0.091°C for module’s temperature, 0.744°C for the surface temperature of the top wall, 0.854°C for the surface temperature of the inner wall and -1.000°C for the surface temperature of the inner wall, respectively. The simulation model, therefore, has a slightly systematic error in underestimation for the module’s temperature, whereas, it is overestimated for the surface temperature of the top wall,

3.2 The effect of spacing of the air gap

The model is simulated continuously over an entire year under the maximum solar radiation of the clear sky condition of Thailand to evaluate the annual amounts of heat transferred through the building, and the annual amounts of photovoltaic electrical energy generation from the photovoltaic panel on the building envelopes. The inclined surface of the photovoltaic panel was tilted at 15°, the air gap varied from 10 mm to 250 mm, with 10mm increment, and the wind speed is fixed at 1 m/s were simulated to investigate the effect of the air gap’s spacing.

The correlation between the annual amounts of heat gains through the building per unit area and the air space is shown in Fig.6. It indicates that the annual amounts of the heat gains penetrated through the top of the building envelop is not a linear proportional to the gap spacing. At a very small air gap, the annual amounts of the heat gains through the building is as high as 209.7 kWh/m², and the heat flux decreases sharply, as the air gap increases until it is at a critical gap of 20 mm, then the annual heat flux increases sharply again, as soon as the air gap increases to another critical gap spacing at 30 mm. At this spacing, the heat flux increases to the second peak of 208.7 kWh/m², which is slightly less than the first peak. Heights of the air gap of which are higher than this gap spacing, the heat flux through the building will gradually decrease with the increasing of the air gap.

The sharp decrease in the annual amounts of heat flux at a very small gap indicates that the heat transfer process is dominated by a heat conduction. The effect of the heat conduction then decreases, because of increasing of the air gap’s heights. However, as the heights of the air gap are large enough, it starts to initiate heat convection in a laminar flow subsequently, and it becomes dominant leading to the increase in the overall heat coefficient. Thereafter, as the spacing increases the value of the heat convection coefficient gradually decreases because the effect of the spacing gap is dominant over the Nusselt number.

In contrast, the annual amounts of the electricity energy generated by the photovoltaic panel is considerably less variation with increasing of the air gap, as comparing it with the annual amounts of the heat flux penetrated through the building envelop. Thus, an increase in the air gap provides a better generation of the annual amounts of photovoltaic electrical energy generated, which is about 0.05 kWh/m².
4. CONCLUSIONS

From this study, it showed that the simulation method developed gives the most accurate results on the prediction on the module’s temperature among all predicted parameters such as temperatures of the air gap, temperatures of the top and internal surface of the wall.

The simulation results for the totally enclosed air gap underneath the photovoltaic panel, which is equivalent to the worst condition, without any ventilation beneath the photovoltaic panel, indicate that the appropriate air gap can reduce the heat flux through the building, which in turn, it could be a load of an air conditioning system of a building, at least 1.85 kWh/m² in a year. However, the air gap does not give any significant effects in increasing amounts of electricity energy generated from a photovoltaic panel. Although the photovoltaic panel can relatively reduce only a small amount of the heat gain through the building, but its good advantage is that it can provide some of clean electricity energy from the photovoltaic, which is about 356 kWh/m² per year.

For the case of Thailand, which an inclined surface of the photovoltaic panel should be tilted at about 15° and wind speed is generally low, a spacing of the appropriate air gap should be more than 40 mm to reduce heat transfer from the back of the photovoltaic panel to the building envelop. In order to minimize the heat gain, a larger air gap is preferred. Although larger air gaps is preferable to give lower heat gains through the building, it should be kept in mind that if the air gap is too large, it could give a negative effect on increasing of heat gain, since it will reduce a projected shaded area due to the slant of solar irradiance incident on the building envelops.
